## 1 **Abstract**

2 Remodeling of collagen fibrils is involved in a variety of physiological and pathological  
3 processes including development, tissue repair, and metastasis. Fibroblast-populated  
4 collagen gel contraction has been employed as a model system to investigate the  
5 collagen fibril remodeling within three-dimensional collagen matrices. Research on  
6 collagen gel contraction is also important for understanding the mechanism underlying  
7 connective tissue repair, and for design considerations for engineered tissues in  
8 regenerative medicine. Second harmonic generation (SHG) is a non-linear optical effect  
9 by which well-ordered protein assemblies, including collagen fibrils, can be visualized  
10 without any labeling, and used for a noninvasive imaging of collagen fibrils in the skin.  
11 Here we demonstrate that the remodeling of collagen fibrils in the fibroblast-populated  
12 collagen gel can be analyzed by SHG imaging with a multiphoton microscope. Two  
13 models of collagen gel contraction (freely versus restrained contraction) were prepared,  
14 and orientation of fibroblasts, density, diameter, and distribution of collagen fibrils were  
15 examined by multiphoton fluorescent and SHG microscopy. Three-dimensional  
16 construction images revealed vertical and horizontal orientation of fibroblasts in freely  
17 and restrained gel contraction, respectively. Quantitative analysis indicated that collagen  
18 fibrils were accumulated within the gel and assembled into the thicker bundles in freely  
19 but not restrained collagen gel contraction. We also found that actomyosin contractility  
20 was involved in collagen fibril remodeling. This study elucidates how collagen fibrils  
21 are remodeled by fibroblasts in collagen gel contraction, and also proves that SHG  
22 microscopy can be used for the investigation of the fibroblast-populated collagen gel.

## 1 **Introduction**

2

3 Collagen provides tensile strength and rigidity to connective tissues of many organs  
4 including the skin, bones, joints, muscles, and blood vessels. These mechanical  
5 properties result from the microstructure, network organization, and orientation of  
6 collagen fibrils that are the assembly of the triple-strand helical structure of fibrillar  
7 collagen molecules (Prockop and Kivirikko, 1995). Indeed, it has been found that the  
8 diameter of collagen fibrils in various tissues are correlated with the tensile strength of  
9 the tissue (Parry et al., 1978). The mechanical properties of tissues also influence lineage  
10 specification of multipotent stem cells (Engler et al., 2006; Mammoto and Ingber, 2009),  
11 and tumor cell migration (Ghajar et al., 2007; Zaman et al., 2006). Hence, the synthesis,  
12 degradation, and remodeling of collagen fibrils by connective tissue cells, including  
13 fibroblasts, osteocytes, and chondrocytes, are involved in a variety of physiological and  
14 pathological processes, and are also implicated in developmental biology, stem cell  
15 biology, and cancer biology.

16

17 Fibroblasts show the ability to contract reconstituted type I collagen gel in which they  
18 are populated (Bell et al., 1979; Grinnell and Lamke, 1984). Although the synthesis and  
19 degradation of collagen molecules do not significantly contribute to the gel contraction  
20 (Guidry and Grinnell, 1987; Mauch et al., 1988), this fibroblast-populated collagen gel  
21 has been employed as the model system to investigate the behaviors of fibroblasts  
22 within three-dimensional collagen matrices, and the remodeling of collagen fibrils by  
23 fibroblasts (Grinnell and Petroll, 2010). Now, research on collagen gel contraction has  
24 become more important for understanding the mechanisms underlying wound closure

1 and repair of connective tissues, and also for design considerations for engineered  
2 tissues in regenerative medicine (Brown and Phillips, 2007; Clark et al., 2007; Grinnell  
3 and Petroll, 2010; Lutolf and Hubbell, 2005).

4  
5 Transmission electron microscopy has revealed that the collagen fibrils are accumulated  
6 proximal to the cells in the fibroblast-populated gel (Grinnell and Lamke, 1984). This  
7 observation has also been confirmed by reflected confocal microscopy of intact collagen  
8 fibrils (Kim et al., 2006), and confocal microscopy of fluorescein isothiocyanate  
9 (FITC)-prelabeled type I collagen (Yamato et al., 1995). However, a recent study has  
10 clearly demonstrated that the signal intensity seen by reflected confocal microscopy  
11 imaging depends on the vertical orientation of the fibrils in the gel, and that reflected  
12 confocal microscopy imaging is not suitable for yielding more complete structural  
13 information of three-dimensional collagen fibrils (Jawerth et al., 2010). In addition, the  
14 confocal images of the gel reconstructed by FITC-prelabeled type I collagen cannot  
15 exclude the signals from disassembled collagen molecules. Therefore, the quantitative  
16 assessment of the collagen fibril remodeling with other imaging modalities is required  
17 to understand the precise mechanism underlying the contraction of the  
18 fibroblast-populated collagen gel.

19  
20 Second harmonic generation (SHG) is a second-order nonlinear optical effect that is  
21 observed in an intense laser field. There, photons interact with noncentrosymmetric  
22 materials and are effectively combined to form new photons with twice the energy. This  
23 process results in the production of a coherent wave at exactly twice the incident  
24 frequency (Campagnola et al., 1999). SHG enables a nondestructive imaging of

1 well-ordered and noncentrosymmetric protein assemblies, such as collagens,  
2 microtubules, and muscle myosins (Campagnola and Loew, 2003). Collagen fibrils,  
3 higher-order polymers of fibrillar collagen molecules, produce a high SHG signal (Roth  
4 and Freund, 1979), and can be visualized in the dermis of the skin with SHG  
5 microscopy (Campagnola et al., 2002; Zipfel et al., 2003). Then, SHG has been utilized  
6 to investigate the organization of collagen fibrils in human skin from healthy volunteers  
7 (Stoller et al., 2002; Sun et al., 2006; Yasui et al., 2004), and patients with scar tissues,  
8 psoriasis, and skin tumors (Brown et al., 2003; Chen et al., 2011; Cicchi et al., 2008;  
9 Konig and Riemann, 2003; Lin et al., 2006), as a noninvasive imaging modality.

10

11 Here, we visualize collagen fibrils in the human dermal fibroblast-populated collagen  
12 gel by SHG imaging and investigate how collagen fibrils are remodeled during collagen  
13 gel contraction.

14

15

## 1 **Materials and methods**

2

### 3 ***Human dermal fibroblast culture***

4 Human dermal fibroblasts were isolated from normal skin tissues, and maintained at  
5 37°C and 10% CO<sub>2</sub> in Dulbecco-Vogt modification of Eagle's medium (DMEM)  
6 (Invitrogen, Carlsbad, CA) containing 10% fetal bovine serum (FBS) (SAFC  
7 Biosciences, Lenexa, KS). The medium was changed every 4 days. Fibroblasts were  
8 used between passages 6 and 9.

9

### 10 ***Inhibitors and reagents***

11 Y-27632 and cytochalasin D were purchased from Wako (Osaka, Japan), and  
12 (-)-blebbistatin from Sigma-Aldrich (St. Louis, MO). Rhodamine-phalloidin was  
13 obtained from Invitrogen.

14

### 15 ***Preparation of fibroblast-populated collagen gels***

16 Collagen gel solution was prepared on ice by mixing Cellmatrix type I-A (acid-soluble  
17 fraction of type I collagen from bovine tendon; Nitta Gelatine, Yao, Japan):  
18 Reconstitution buffer (Nitta Gelatine): 5 x DMEM (Sigma-Aldrich) in a ratio of 7:1:2.  
19 Fibroblasts cultured until subconfluent were trypsinized, and suspended with culture  
20 medium. Cells were counted and centrifuged to prepare a suspension at a concentration  
21 of 10<sup>6</sup> cells/ml in DMEM. Four volumes of the collagen gel solution were added to 1  
22 volume of the cell suspension. The final concentrations of collagen and cells were 1.68  
23 mg/ml and 2x10<sup>5</sup> cells/ml, respectively. The final mixture (500 µl /well) was added to  
24 each well of 24-well tissue culture plates (#3820-024 with normal adhesion surface and

1 EZ-BindShut II #4820-800LP with low adhesion surface; IWAKI, Shizuoka, Japan).  
2 After 1 hour of incubation at 37°C and 10% CO<sub>2</sub>, 1ml per well of culture medium  
3 containing FBS was added with and without pharmacological inhibitors. The final  
4 concentrations of Y-27632, (-)-blebbistatin, and cytochalasin D were 10 μM, 10 μM,  
5 and 100 nM, respectively. After 2 days of incubation at 37°C and 10% CO<sub>2</sub>, the collagen  
6 gel was fixed with 3.7% buffered formaldehyde phosphate-buffered saline (PBS), and  
7 observed with a multiphoton microscope.

8

### 9 ***Rhodamine-phalloidin staining***

10 The collagen gel was fixed with 3.7% buffered formaldehyde in PBS at 4°C for 1 hour,  
11 treated with 0.1% Triton-X-100 in PBS for 10 min, and subsequently washed with PBS.  
12 The gel was then incubated with 4 units/ml rhodamine-phalloidin for 30 min, and  
13 washed with PBS overnight. The stained gel was observed with a multiphoton  
14 microscope.

15

### 16 ***Multiphoton microscopy***

17 Multiphoton imaging was performed with a galvano scanner (A1R MP; NIKON, Tokyo,  
18 Japan) giving 512x512 pixel frames at 0.5Hz by using a NIKON 25x NA 1.1 water  
19 immersion objective lens. A mode-locked infrared laser line at 950 nm was used,  
20 originating from a dispersion-corrected high power Ti-Sapphire laser (Mai Tai HP  
21 DeepSee; Spectra-Physics, Tokyo, Japan) together with optical filters 483/32 for SHG  
22 (Semrock, Rochester, NY), 594LP for tetramethylrhodamine (TMR) emission  
23 (Semrock), 511LP for SHG/TMR detection splitting.

24

### 1 ***SHG imaging***

2 The SHG signal at 475 nm was detected by a GaAsP photomultiplier tube, using a  
3 narrow-band pass filter (483/32, Semrock). The wavelength of the pumping laser was  
4 chosen to be 950 nm to minimize autofluorescence signals and suitable for TMR  
5 excitation. We set a dielectric-coated concave mirror (CM508-050-E02; Thorlabs,  
6 Newton, NJ) on the Z-axis slide stage (TSD-603; Sigma Koki, Tokyo, Japan), and  
7 searched the adjust position of concave mirror to detect SHG signals.

8

### 9 ***Image analysis***

10 Obtained images were analyzed with Fiji (Schindelin et al., 2012). A sequence of  
11 Z-stack images was reconstituted with NIS-Elements (NIKON). The relative intensity  
12 of SHG signals was calculated by the sum of SHG signal intensity of all pixels from a  
13 single microscopic image. The experimental values were obtained from a number of  
14 images in each experiment (See Figure legends). The diameter of individual SHG  
15 signals was defined as the length of the minor axis of well-isolated each SHG signal.  
16 The experimental values were obtained from 20 SHG signals from each condition.

17

### 18 ***Statistical analysis***

19 The values are expressed as means  $\pm$  s.d.. *p* value was calculated by two-tailed Student's  
20 t-test. Values with  $p < 0.05$  were considered statistically significant.

21

## 1 **Results**

2

### 3 *Differences in the orientation of fibroblasts in floating and anchored collagen gel* 4 *contraction*

5 We developed two models of human dermal fibroblast-populated collagen gel  
6 contraction. The first model was a floating collagen gel contraction; the  
7 fibroblast-populated collagen gel was prepared in a microwell with low adhesion  
8 surface (Fig. 1A). In this model, gel contraction occurs when cell-containing gels are  
9 released from the culture surface soon after collagen polymerization (Grinnell, 2000).  
10 The other model was an anchored collagen gel contraction; the fibroblast-containing  
11 collagen gel was made in a microwell with normal adhesion surface (Fig. 1A). In the  
12 second model, restrained gel contraction occurs because the collagen gel remains  
13 attached to the plastic culture surface and cell-matrix tension are generated (Grinnell,  
14 2000). All gels were incubated for 48 hours after preparation. In the floating contraction  
15 model, the gel markedly decreased its diameter, however, contraction was completely  
16 inhibited in the restrained contraction model (Fig. 1B). The collagen gel without  
17 fibroblasts did not show any contractile activity, even if it was prepared in a microwell  
18 with low adhesion surface (Fig. 1B).

19

20 We first investigated whether the two distinct modes of collagen gel contraction change  
21 the organization of fibroblasts in the gels. The fibroblast-populated gels incubated for 48  
22 hours were fixed and stained with rhodamine-phalloidin, and then cells were visualized  
23 by multiphoton fluorescent microscopy. The construction of three-dimensional images  
24 revealed vertical orientation of fibroblasts in floating collagen gels (Fig. 1C). On the

1 contrary, cells in adherent collagen gels were predominantly distributed along the  
2 horizontal axis, with the highest tension between fibroblasts and collagen lattice (Fig.  
3 1D). These results indicated that human dermal fibroblasts changed their orientation in  
4 the gels by sensing cell-matrix tension.

#### 6 ***Experimental setting for SHG imaging of the fibroblast-populated collagen gel***

7 The collagen gel, held by an agarose gel, was mounted on the stage of an upright  
8 multiphoton microscope. In our experimental setting, the signals from specimens were  
9 detected through the objective lens (Fig. 2A and B). However, the phase-coherent SHG  
10 light has a forward propagating nature, and a transmission mode of detection is required  
11 to obtain a significant amount of SHG signals. Although the backscattering SHG light  
12 could be detected in our setting, the intensity of SHG signals of collagens in the gel was  
13 very low even if the laser power was absolutely high (Fig. 2C). To obtain better SHG  
14 images, we set a concave mirror under the collagen gel held by an agarose gel to reflect  
15 the transmitted SHG light into the objective lens (Fig. 2A and B). The gathering of  
16 transmitted and backscattering SHG light by using the mirror significantly enhanced  
17 SHG signals, which achieved the better SHG imaging of the collagen fibrils in the gel  
18 (Fig. 2C).

#### 20 ***Remodeling of collagen fibrils in the freely and restrained collagen gel contraction***

21 We next measured the intensity of SHG signals from collagen fibrils in floating and  
22 adherent collagen gels by SHG microscopy, which was optimized for collagen gels (Fig.  
23 2). Whereas a large amount of SHG signals were detected in the floating gel contraction  
24 model, the signals were very faint in the anchored collagen gel contraction model (Fig.

1 3A). Quantitative analysis clearly revealed a 4-fold increase in SHG lights from the  
2 floating gels against those from the anchored gels (Fig. 3B). Furthermore, the anchored  
3 collagen gels showed a 2-fold increase in SHG signals against collagen gels not  
4 containing fibroblasts (Fig 3B). We next measured the diameter of individual SHG  
5 signals in each condition. The signals from the floating and anchored gels had  $1.62 \pm$   
6  $0.335 \mu\text{m}$  (mean  $\pm$  s.d.) and  $1.05 \pm 0.261 \mu\text{m}$  (mean  $\pm$  s.d.) in diameter (Fig. 3C). When  
7 fibroblasts were not populated in the collagen gels, SHG signals were  $0.778 \pm 0.124 \mu\text{m}$   
8 (mean  $\pm$  s.d.) in diameter (Fig. 3C). The quantitative analysis of SHG signals revealed  
9 that human dermal fibroblasts had the ability to assemble the collagen fibrils in the gels,  
10 and that this activity was enhanced in freely collagen gel contraction.

11

### 12 ***Distribution of collagen fibrils in the freely and restrained collagen gel contraction***

13 It has been reported that the collagen fibrils are accumulated proximal to the cells in the  
14 fibroblast-populated gel as observed by transmission electron microscopy (Grinnell and  
15 Lamke, 1984). However, it is difficult to obtain wide area images and quantitative data  
16 with this method. Therefore, we examined the distribution of collagen fibrils in freely  
17 and restrained collagen gel contraction models. The fibroblast-populated gels were fixed  
18 and stained with rhodamine-phalloidin, and then cells and collagen fibrils were  
19 visualized by multiphoton fluorescent and SHG microscopy, respectively. In the floating  
20 collagen gels, SHG signals significantly accumulated around rhodamine-positive cells  
21 (Fig. 4A). The quantitative analysis of rhodamine and SHG signals revealed that the  
22 collagen fibrils accumulated within approximately  $20 \mu\text{m}$  proximal to the cells in the  
23 gels (Fig. 4A). In contrast, the accumulation of collagen fibrils around fibroblasts was  
24 not observed in the anchored collagen gels (Fig. 4B). These data clearly demonstrated

1 that collagen fibrils were accumulated proximal to the cells by human dermal fibroblasts  
2 in the freely contracting collagen gel.

#### 3 4 ***Actomyosin contractility is required for collagen fibril remodeling***

5 Attenuation of actin polymerization with cytochalasin B has inhibits collagen gel  
6 contraction (Nogawa and Nakanishi, 1987). Inhibition of ROCK activity has also results  
7 in the decreased contraction of the collagen gels (Kim et al., 2006). ROCK regulates  
8 both actin polymerization and MLC phosphorylation, under Rho subfamily GTPases  
9 (Amano et al., 2010; Maekawa et al., 1999). Finally, we examined whether actomyosin  
10 contractility is involved in the remodeling of collagen fibrils. ROCK inhibitor Y-27632,  
11 myosin ATPase inhibitor (-)-blebbistatin (Blebb), and actin polymerization inhibitor  
12 cytochalasin D (CytoD) reduced the contractile activity of collagen gels by fibroblasts  
13 in the floating gel (Fig. 5A). Inhibition of actomyosin contractility and actin  
14 polymerization modestly changed the angle of cells against the horizontal plane in both  
15 collagen gel contraction models (Fig. 5B). However, SHG intensity and the diameter of  
16 SHG signals were significantly decreased by treatment with Y-27632, Blebb, and CytoD  
17 in the floating, but not in the anchored, collagen gels (Fig. 5C and D). These results  
18 indicated that the assembly of collagen fibrils in freely collagen gel contraction required  
19 actomyosin contractility.

20

21

22

## 1 **Discussion**

2

3 Fibroblast-populated collagen gel contraction has been studied for more than three  
4 decades; however, the mechanism behind this process is still unclear. This is at least in  
5 part due to difficulty in visualization of collagen fibrils in three-dimensional collagen  
6 matrices. In this study, we demonstrated that SHG imaging visualized the collagen fibril  
7 network without any labeling in the gel and that the quantitative image analysis  
8 dissected remodeling of collagen fibrils in the fibroblast-populated collagen gel. This  
9 work has three major findings concerning collagen gel contraction. First, fibroblasts  
10 show vertical orientation in freely gel contraction, but are distributed along the  
11 horizontal axis in response to extracellular tension in restrained contraction. Second,  
12 collagen gel contraction involves both the accumulation of collagen fibrils proximal to  
13 the cells, and the assembly of collagen fibrils into the thicker bundles. Third,  
14 actomyosin contractility is required for the accumulation and assembly of collagen  
15 fibrils.

16

17 Concerning the mechanism of collagen gel contraction, Yamato and colleagues (Yamato  
18 et al., 1995) have hypothesized that fibroblasts extend cellular protrusions and attach  
19 collagen fibrils to them by making the collagen-integrin-cytoskeleton complexes, and  
20 that subsequent withdrawal of the protrusions results in the accumulation of collagen  
21 fibrils in the vicinity of the plasma membrane. These processes could explain collagen  
22 gel contraction by fibroblasts. In fact, attachment of collagen fibrils to cellular  
23 protrusions containing microfilaments has been observed by transmission electron  
24 microscopy (Grinnell and Lamke, 1984). Our results reinforce this hypothesis. We

1 demonstrated quantitatively that collagen fibrils accumulated around the fibroblasts, and  
2 assembled into the thicker bundles in freely gel contraction, which required actomyosin  
3 contractility. In anchored collagen gels, fibroblasts might not be able to draw collagen  
4 fibrils against the external tensions. We also found changes in the orientation of  
5 fibroblasts in floating and anchored collagen gels. Although the involvement of cell  
6 orientation in gel contraction was not clear, the longitudinal axis of fibroblasts was  
7 perpendicular in relation to the direction of contraction in both floating and anchored  
8 collagen gels. This means that the large surface area of the cells is available for forming  
9 cellular protrusions to accumulate collagen fibrils in the vicinity of the plasma  
10 membrane.

11

12 To validate the hypothesis described above, and comprehend the precise mechanism  
13 underlying the contraction of the fibroblast-populated collagen gel, live-imaging of  
14 fibroblasts and associated collagen fibrils in the gel is definitely crucial. The  
15 combination of multiphoton fluorescent and SHG microscopy is widely used for  
16 nondestructive imaging of living tissues (Campagnola et al., 2002; Cicchi et al., 2008;  
17 Zipfel et al., 2003). In the present study, however, the high laser power was required to  
18 detect SHG signals from collagen gels, which caused the local heating effects and  
19 damaged the fibroblasts in the gel. Systems comprising laser irradiation and SHG  
20 detection should be improved to achieve SHG live-imaging of the fibroblast-populated  
21 collagen gel.

22

23 This study showed that remodeling of collagen fibrils required actomyosin contractility  
24 of fibroblasts. We have previously demonstrated that actin filaments were remodeled

1 during conversion from a human epidermal keratinocyte stem cell to its progeny with  
2 restricted growth potential, and that actin filament dynamics and actomyosin  
3 contractility were involved in maintenance of keratinocyte stem cells in vitro (Nanba et  
4 al., 2013). Importantly, the difference in collagen gel contractile activity is correlated  
5 with replicative aging of fibroblasts (Bell et al., 1979). Recent studies have revealed the  
6 existence of multipotent stem/progenitor cells in the skin dermis (Kuroda et al., 2010;  
7 Toma et al., 2001; Wong et al., 2006). Collagen gel contractile activity, an indicator of  
8 actomyosin contractility of cells, might be associated with proliferative capacity and  
9 multipotency of dermal fibroblasts. Understanding and controlling of collagen  
10 contractile ability also improve the transplantation of engineered tissue equivalents,  
11 since contractile activity of such equivalents is a recurring problem in skin-graft  
12 transplantation (MacNeil, 2007). Furthermore, mechanical loading to cutaneous wounds  
13 reduces scar formation (Gurtner et al., 2011; Wong et al., 2012). Hence, research on  
14 fibroblast-populated collagen gel contraction is definitely implicated in regenerative  
15 medicine of the skin and other organs.

16

17 In conclusion, our data demonstrated here that SHG microscopy achieved the  
18 visualization of the remodeling of collagen fibrils without any labeling in the gel, and  
19 revealed the remodeling of collagen fibrils in collagen gel contraction. These points are  
20 significant for advances in the investigation of collagen gel contraction.

1 **Figure Legends**

2

3 **Fig. 1**

4 Freely and restrained collagen gel contraction. (A) A schematic drawing of two models  
5 of fibroblast-populated collagen gel contraction. Freely collagen gel contraction occurs  
6 when the gel is prepared in a well of 24-well plate with low adhesion surface.  
7 Restrained gel contraction occurs when the gel is prepared in a well with normal  
8 adhesion surface that remains attached the gel to the culture surface. (B) Photograph of  
9 gels after 2 days incubation. Air bubbles remained within the gel without cells. (C and  
10 D) Left panel shows three-dimensional reconstruction images of fibroblasts in the  
11 floating (C) and anchored (D) collagen gel. The gel was fixed and stained with  
12 rhodamine-phalloidin to visualize cells. Right panel shows distribution of angles of the  
13 longitudinal axis of fibroblasts against the horizontal plane in the floating (C) and  
14 anchored (D) collagen gel. The distributions were obtained from 33 and 36 cells in C  
15 and D, respectively. Bars, 100  $\mu\text{m}$ .

16

17 **Fig. 2**

18 Experimental setting for SHG imaging of the fibroblast-populated collagen gel. (A) A  
19 schematic diagram of our mutiphoton microscope for the collagen gel SHG imaging.  
20 (B) Photograph of our experimental setting. A concave mirror was set under the  
21 collagen gel held by an agarose gel. (C) Left panel shows the SHG images of the  
22 floating collagen gels with and without the concave mirror. Right panel shows  
23 quantitative analysis of SHG intensity in each condition. The values were obtained from  
24 9 images from each condition. Bar, 100  $\mu\text{m}$ . \*\*\*,  $p < 0.001$ .  $p$  value was calculated by

1 two-tailed Student's t-test.

2

### 3 **Fig. 3**

4 Quantitative analysis of SHG signals from floating and anchored collagen gels. (A)

5 Three-dimensional reconstruction of SHG images of floating and anchored collagen

6 gels. Bars, 50  $\mu$ m. (B) Quantitative analysis of SHG intensity in each condition. The

7 values were obtained from 33 images from each condition. (C) Quantitative analysis of

8 diameter of SHG signals in each condition. The values were obtained from 20 collagen

9 fibrils from each condition. \*\*,  $P < 0.01$ . \*\*\*,  $p < 0.001$ .  $p$  value was calculated by

10 two-tailed Student's t-test.

11

12

### 13 **Fig. 4**

14 Distribution of collagen fibrils and fibroblasts in floating and anchored collagen gels. (A

15 and B) Quantitative analysis of three-dimensional reconstruction of SHG and

16 multiphoton fluorescent images of floating (A) and anchored (B) collagen gels.

17 Fibroblasts were visualized by rhodamine-phalloidin staining.

18

### 19 **Fig. 5**

20 Effects of inhibition of actomyosin contractility on collagen fibril remodeling. (A)

21 Inhibition of freely collagen gel contraction by Y-27632 (10  $\mu$ M), (-)-blebbistatin

22 (Blebb) (10  $\mu$ M), and cytochalasin D (CytoD) (100 nM). (B) Distribution of angles of

23 the longitudinal axis of fibroblasts against the horizontal plane in the floating (left) and

24 anchored (right) collagen gel in the presence of inhibitors. The distributions were

1 obtained from at least 10 cells from each condition. (C) Quantitative analysis of SHG  
2 intensity in the presence of inhibitors. The values were obtained from at least 11 images  
3 from each condition. (C) Quantitative analysis of diameter of SHG signals in the  
4 presence of inhibitors. The values were obtained from 20 collagen fibrils from each  
5 condition. \*,  $p < 0.05$ , \*\*,  $p < 0.01$ , and \*\*\*,  $p < 0.001$  for the difference between  
6 control *versus* each inhibitor.  $p$  value was calculated by two-tailed Student's t-test.
